Nucleophilic degradation of Diazinon in thermoreversible polymer-polymer aqueous biphasic systems

Daniela Millan,a,b Mafalda R. Almeida,a,b Ana F.C.S. Rufino,b João A.P. Coutinho,b Mara G. Freireb*

Although aqueous biphasic systems have been largely investigated in the separation and/or purification of biocompounds, their potential as reaction media to design integrated reaction-separation processes has been less explored. In this work aqueous biphasic systems (ABS) composed of polypropylene glycol of molecular weight 400 g.mol⁻¹ (PPG 400) and different polyethylene glycols (PEG) were characterized, and investigated as integrated reaction-separation processes, i.e. in the nucleophilic degradation of Diazinon and further separation of reaction products by taking advantage of these ABS lower-critical solution temperature (LCST) behaviour. The nucleophilic degradation of Diazinon was carried out at the monophasic regime at 298 K, after which an increase in temperature (up to 313 K) allowed the products separation by two-phase formation (thermoreversible systems). The reaction kinetics and reaction pathways have been determined. The reaction kinetics increase as the PEG molecular weight decreases, with the half-lives values obtained being competitive to those previously reported using volatile organic solvents as solvent media and significantly higher than under alkaline hydrolysis. One reaction pathway occurs in ABS comprising PEGs of higher molecular weight, whereas in ABS composed of PEG 600 two reaction pathways have been identified, meaning that the reaction pathways can be tailored by changing the PEG nature. ABS formed by PEGs of lower molecular weight were identified as the most promising option to separate the pesticide degradation products by simple applying changes in temperature.

Introduction

Aqueous biphasic systems (ABS) have been largely investigated in the separation and purification of biocompounds, this technique is relatively simple and inexpensive, of easy operation, scalable, and allows the purification and concentration stages to be integrated in a single step. Despite their relevance in this field, their potential as reaction media to design integrated reaction-separation systems has been seldom investigated. These systems consist on two aqueous phases based on polymer-polymer, polymer-salt, or salt-salt combinations. Both solutes are water-soluble, separating into two coexisting phases above a given concentration, with one of the aqueous phases being enriched in one of the solutes whereas in the other phase there is a prevalence of the second polymer or salt.

Conventional ABS are formed by polymer-salt or polymer-polymer mixtures and have been studied for more than five decades; yet, polymer-polymer systems are the choice of preference for the separation, recovery and purification of solutes sensitive to an ionic environment, such as biomolecules, since these systems have a low/negligible ionic strength. In these systems, polyethylene glycol (PEG) is commonly used as one of the phase-forming components due to its high biodegradability, low toxicity, low volatility, low melting temperature, large water miscibility and low cost, being commercially available in a wide range of molecular weights. Polypolypropylene glycol (PPG) shares some of the PEG advantages, and can be used as well as an ABS phase-forming component. Accordingly, PEG and PPG were here selected as ABS phase-forming components to minimize the negative impacts of salts to carry out the nucleophilic reaction herein studied.

Environmental contamination and bioaccumulation of pesticides in soils and groundwater is a widespread ecological problem. Pesticides are widely used to enhance food production in agricultural practice and, in a lesser extent, to control unwanted pests and disease vectors in public health. However, they cause several health hazards and have a tremendous environmental impact. Organophosphorous (OP) pesticides are the most used worldwide and their metabolites are widespread across different populations. The use of strong oxidants or nucleophiles is among the methods most used for their destruction. Diazinon is an OP pesticide that has a P=S electrophilic center (Scheme 1). It has been demonstrated that OPs show different reaction pathways when they are breakdown by N nucleophiles, as piperidine. They can exhibit up
to three reaction pathways, resulting in a large variety of reaction products.\textsuperscript{16} The degradation pathway depends strongly on the reaction media. However, when the nucleophile is piperidine two main reaction pathways (see Scheme 1) depending on the solvent nature have been described.\textsuperscript{17} Furthermore, a recent report\textsuperscript{18} showed that when the nucleophilic degradation of paraoxon, another OP pesticide, is carried out in aqueous solutions of ionic liquids the selectivity of the reaction is strongly dependent on the water amount. In this type of reactions, the degradation products separation is a difficult task since some of these products are unstable and susceptible to other nucleophilic attack. On the other hand, considering the potential toxicity of OPs and related metabolites and subproducts, the finding of efficient removal methods of these compounds is a pivotal action.

In this work, ABS formed by PPG and PEG aqueous mixtures (at their monophasic regimes) were studied as reaction media for the nucleophilic degradation of Diazinon, while taking advantage of the effect of temperature to induce two-phase formation (thermoresversible systems) to achieve the separation of the reaction products from the reaction medium. The effect of solvents on the reaction was investigated. The ABS phase diagrams at several temperatures were determined to infer the mixtures compositions and temperatures needed to be applied to take advantage of their thermoresversible behavior. The ABS thermoresversible performance to carry out the reaction and proceed with the separation of the reaction products was finally appraised.

Scheme 1. Reaction pathways for the nucleophilic degradation of Diazinon.

Methodology

Chemicals

The ABS studied in this work were established by using an aqueous solution of polypropylene glycol of molecular weight 400 g mol\textsuperscript{-1}, PPG 400, from Aldrich, and solutions of several PEGs. The PEGs studied were of molecular weight 600 g mol\textsuperscript{-1}, 1000 g mol\textsuperscript{-1}, 2000 g mol\textsuperscript{-1}, 4000 g mol\textsuperscript{-1}, 6000 g mol\textsuperscript{-1}, 8000 g mol\textsuperscript{-1}, 10000 g mol\textsuperscript{-1} and 20000 g mol\textsuperscript{-1}, here abbreviated as PEG 600, PEG 1000, PEG 2000, PEG 4000, PEG 6000, PEG 8000, PEG 10000 and PEG 20000, respectively. PEG 600 and PEG 1000 were acquired from Alfa Aesar, PEG 6000 was purchased from Acros, PEG 2000 and PEG 8000 were supplied by Sigma, and the remaining polymers from Fluka. All polymers were described as pure. Piperidine (99.5%) was distilled before use. Diazinon (100% pure, analytical standard) was purchased from Aldrich. The water employed was double distilled, passed across a reverse osmosis system and finally treated with a Milli-Q plus 185 water purification apparatus, with a conductivity of 1.60 ± 0.18 µS/cm.

Phase diagrams

The binodal curve of each phase diagram was determined through the cloud point titration method at several temperatures, namely 288, 298, 308 and 313 K (±1 K), and at atmospheric pressure. The temperature was controlled through a temperature-controlled water bath with a precision of 0.01 K. The experimental method used is detailed elsewhere.\textsuperscript{19} Aqueous solutions of PPG 400 and PEGs at 90 wt% and from 40 to 70 wt%, respectively, were used in the determination of the PPG-PEG-water ternary phase diagrams. The repetitive dropwise addition of each PEG aqueous solution into the aqueous solution of PPG 400 was carried out until the detection of a cloudy (biphasic) solution, followed by the dropwise addition of ultrapure water until the observation of a limpid solution (monophasic region). All additions were made under continuous stirring. The binodal curves were determined by the weight quantification of all components added (±10\textsuperscript{-4} g).

Partition of Diazinon

From the phase diagrams determined, ternary mixtures composed of 35 wt% PPG 400 + 15 wt% each PEG + 50 wt% H\textsubscript{2}O (total mass of 2.0 g) were prepared to carry out the partition of Diazinon, aiming at identifying the most promising ABS to develop an integrated reaction-separation process. Ca. 2.0 mg of Diazinon was added directly to each ABS and the mixture vigorously stirred until complete solubilization. The phase separation of the ABS was induced by heating and centrifuging the mixture at 313 K at 3000 rpm, during 30 min. After, a careful separation of the phases was performed, and the Diazinon in each phase was quantified by UV-spectroscopy using a BioTeck Synergy HT microplate reader at a wavelength of 247 nm, using a previously established calibration curve. The extraction efficiencies (EE\%) of Diazinon, defined as the percentage ratio between the amount of Diazinon in the PPG-rich aqueous phase and that in the two phases, were determined for each ABS comprising a different PEG. At least three independent ABS were prepared, and three samples of each phase were quantified. Control or “blank” solutions at the same mixture point used for the extraction studies (with no pesticide added) were used in all systems.

Diazinon nucleophilic degradation

Nucleophilic reactions were performed in three ABS, formed by 35 wt% PPG 400 + 15 wt% PEG (600, 2000 and 20000) + 50 wt% H\textsubscript{2}O (total mass of 2.0 g). Each mixture was vigorously stirred and left at room temperature until a homogeneous mixture was observed. The pesticide (7.5 mg) and nucleophile (piperidine, 21.3 mg) were added to the mixture, stirred and left at room temperature...
temperature. Each mixture was made in triplicate. The kinetic reaction was monitored by $^{31}$P NMR on a 400 MHz spectrometer following the disappearance of the pesticide signal. Spectra were recorded at different reaction times until the pesticide signal completely disappeared. Then, the phases separation of the thermoreversible ABS was induced by heating up the mixture to 313 K during 30 min. Afterwards, the bottom and top phases were carefully separated and analyzed by $^{31}$P-NMR and ESI-MS to identify the reaction products present in each phase.

Results and discussion

Phase diagrams

To evaluate different possibilities and further select the most adequate system to carry the degradation of Diazinon, ternary phase diagrams were determined for various PEGs (PEG 600, 1000, 2000, 4000, 6000, 8000, 10000 and 20000) + PPG 400 + water, at 298 K (±1 K) and at atmospheric pressure. The respective ternary phase diagrams are illustrated in Fig. 1, represented in orthogonal coordinates in which the water content corresponds to the difference to reach 100 wt%. Each point provided in the phase diagrams corresponds to a determined experimental solubility point, which is used to describe the binodal or solubility curve of each phase diagram. The solubility curve separates the monophasic region (below the curve) from the biphasic region (above the curve), i.e. at mixture compositions above the bimodal curve there is the formation of two immiscible phases. The experimental weight fraction data of each phase diagram and the adjusted parameters and respective fitting of the experimental data are reported in the ESI. Some of these systems, namely comprising PEG 600, 2000, 4000 and 6000, were previously reported, being the results here obtained in close agreement with the literature, with an average standard deviation of 2.2 wt% – cf. Table S5 in the ESI with the respective data.

Fig. 1 shows the effect of the molecular weight of PEG in the ABS formation. Overall, for PEGs of lower molecular weight, phase separation requires higher quantities of PPG to occur, with the ability to form ABS at a fixed PPG concentration increasing in the following order: PEG 600 + PEG 1000 + PEG 2000 < PEG 4000 < PEG 6000 < PEG 8000 < PEG 10000 < PEG 20000. Similar conclusions were reported by Sadeghi and Maali in PEG 400 + PEG 600/2000/4000/6000 + water liquid-liquid systems. Similar behaviors were observed in other ABS composed of PEG/salt,19,21 or PEG/IL pairs.22 This tendency is a consequence of the increase in hydrophobicity displayed by PEGs with higher molecular weight. As discussed by Sadeghi and Maali, the preferentially hydration complexes formed between the more hydrophilic polymer (PEG) and water molecules cause the exclusion of PEG from the near surface region of the more hydrophobic PPG polymer in solution. This exclusion effect increases by increasing the concentration of both polymers and by increasing the PEG molecular weight so that phase formation becomes more entropically favorable.
Phase diagrams of PEG 600 or PEG 20000 + PPG 400 + water was evaluated. The phase diagrams of these systems at 288, 298, 308 and 313 K (± 1 K) and atmospheric pressure were determined and are represented in Figs. 2 and 3. The experimental weight fraction data of each phase diagram are reported in the ESI. With both PEGs, the ability of PPG 400 to form ABS in the presence of a fixed PEG concentration increases in the following temperature order: 288 K < 298 K < 308 K < 313 K. Overall, the required polymers concentration to form a biphasic system decreases by increasing the temperature, following a lower critical solution temperature (LCST) behavior. This behavior is particularly due to the PPG 400 hydrophobicity that increases with temperature\(^{23}\) and, therefore, the required concentration of PEG to form a second phase decreases. The same behavior was observed by Sadeghi and Maal\(^{24}\) with PPG + PEG + water and PPG + PEGDMEs (polyethylene glycol di methyl ether) + water systems. At lower temperatures, low-energy polar conformations are present in the polymers, leading to a higher aqueous solubility and a lower ability to form ABS; on the other hand, at higher temperatures a higher energy and less polar conformations are favored, increasing the ability to form ABS.\(^{20}\) Overall, at higher temperatures, hydration shells around the polymer are less developed and the entropy of mixing increases, favoring the ABS formation.

**Partition of Diazinon**

The effect of PEG molecular weight in the partition of Diazinon in ABS formed by 35wt\% PPG 400 + 15wt\% PEG + 50 wt\% H\(_2\)O was firstly evaluated at 313 K (± 1 K) to gather preliminary information on promising systems to carry out the integrated degradation-separation process. The extraction efficiencies (EE\%) of Diazinon, which correspond to the percentage ratio between the amount of Diazinon in the PPG-rich aqueous phase and that in the two phases, in the different ABS studied are shown in Fig. 4 (detailed results of which are given in the ESI). In all systems, Diazinon preferentially partitions to the most hydrophobic phase, that is, the PPG-rich phase, with extraction efficiencies ranging between 54.5% and 93.7%. The logarithm of the octanol–water partition coefficient of Diazinon, log(K\(_{ow}\)) = 3.81,\(^{24}\) supports this pesticide high hydrophobicity and preferential partition to the PPG-rich phase. Although an increase in the EE\% of Diazinon to the PPG-rich phase is visible when increasing the PEG molecular weight from 600 to 2000 g.mol\(^{-1}\), results obtained with ABS formed by PEGs with a molecular weight equal and higher than 2000 are similar (86.6\%-93.7\%), suggesting that after a certain threshold the increase in the PEGs molecular weight has a negligible influence in the Diazinon partition to the PPG-rich phase. Considering the extraction efficiencies of Diazinon in all the ABS studied, the systems composed of PPG 400 + PEG (600, 2000 and 20000) + H\(_2\)O were selected to perform the reaction of nucleophilic substitution of Diazinon. The selection of the three PEGs will allow to evaluate the molecular weight of the polymer and viscosity of the medium in the nucleophilic degradation of diazinon, while taking into account the different partition trends obtained.

**Nucleophilic substitution reactions of Diazinon in ABS**

The nucleophilic degradation of Diazinon and the recovery of the products was carried out in three ABS, as described above, composed of 35 wt\% PPG 400 + 15 wt\% PEG (600, 2000 and 20000) + 50 wt\% H\(_2\)O. Each one of these systems were used as reaction medium to perform the nucleophilic substitution reaction of Diazinon with piperidine. These reactions were carried out at 298 K under pseudo-first order conditions (at least 10 fold excess of piperidine) to compare the results with those previously reported in other reaction media.\(^{17,25}\) The kinetic of Diazinon’s disappearance in these mixtures was followed by \(^{31}\)P-NMR at room temperature, whose results are given in Figs. 5-7. From these data, plots of log(%degradation) vs time were used to calculate the pseudo-first order constants (k\(_{obs}\)) in all solvents - the k\(_{obs}\) values obtained for each ABS are shown in Table S1 in the ESI. The used equations and kinetics details are given in the ESI. The half-lives (t\(_{1/2}\)) calculated from the pseudo-first order constants (k\(_{obs}\)) showed in Table S11 in the ESI increase as the PEG molecular weight decreases, i.e., PEG 20000 (t\(_{1/2}\) = 1851 min) < PEG 2000 (t\(_{1/2}\) = 1273 min) < PEG 600 (t\(_{1/2}\) = 927 min). It is well known that viscosity of polymer solutions increases with the molecular weight increase, which could affect the reaction kinetics. Furthermore, as a consequence of the higher PEG molecular weight, a different packing degree of the solvent system could lead to a different solvation degree of reagents,\(^{26}\) and thus influence reaction kinetics as well.

The half-lives (t\(_{1/2}\)) values obtained here were compared with those reported previously in other solvents at the same experimental conditions.\(^{17,25}\) This comparison reveals that PEG-PPG aqueous solutions can be used as promising alternative reaction media to the nucleophilic degradation of Diazinon. For example, the t\(_{1/2}\) values reported in imidazolium-based ionic liquids range between 71 min and 700 min, while in organic solvents such as MeOH, MeCN and Dioxane these values are 973 min, 1175 min and 2204 min, respectively. Although bio-based solvents have been previously attempted, such as propylene carbonate, the nucleophilic degradation of Diazinon was not found to occur.\(^{17}\) The t\(_{1/2}\) values obtained in the current
work are similar to those obtained with hazardous volatile organic solvents, yet using aqueous solutions of non-volatile and environmentally-friendly polymers. From the $^{31}$P-NMR spectra shown in Figs. 5-7 it can be depicted that as the signal of Diazinon decreases (60 ppm) two new phosphoryl signals appear at 55 and 50 ppm in the PEG 600 + PPG 400 + water mixture, while there is only one new phosphorous signal at 55 ppm in the PEG 2000 and 20000 comprising mixtures. To characterize these NMR signals, product analysis by $^{31}$P-NMR and ESI-MS was performed. According to the results here obtained and the literature,$^{17,20}$ the two phosphoryl signals at 55 and 50 ppm were assigned to diethylthiophosphate (2) and O-ethyl-O-[4-methyl-6-(propan-2-yl)pyrimidin-2-yl]thiophosphate diester (4), respectively in Scheme 1. Compound 2 is produced in the aromatic pathway (SN$_2$AR) by nucleophilic attack at C-1 carbon of the Diazinon’s aromatic ring, and product 4 is produced in the aliphatic pathway (SN$_2$C) by an attack at the aliphatic carbon of the O-ethyl group of Diazinon - cf. Scheme 1. Regarding the non-phosphorylated products, the ESI-MS spectra (Figure S2 in the ESI) is in agreement with the structures show in Scheme 1 for compounds 3 and 5. For ABS formed by PEG 600 both reaction pathways SN$_2$R and SNC take place, while in the monophasic regimes of ABS comprising PEG 2000 or PEG 20000, only the SN$_2$AR reaction pathway was observed.

Fig. 5 Stacked $^{31}$P-NMR spectra for the nucleophilic degradation of Diazinon with piperidine performed in a mixture of 35 wt% PPG 400 + 15 wt% PEG 600 + 50 wt% H$_2$O at 298K.

It is important to mention that the diethylthiophosphate (2) visible at 55 ppm, is the same product found in the acid or basic hydrolysis of Diazonon.$^{27}$ Since the mixtures here studied contain 50 wt% water the main reaction product seen in Fig. 5-7 is the one found at 55 ppm, diethylthiophosphate (2). It is interesting to observe that when the PEG 600 mixture was used as solvent there are two phosphoryl products at 55 ppm and 50 ppm. This suggests that the reaction pathway and its $t_{1/2}$ are dominated by the transfer phenomena. These results shown that it would be possible to control the reaction pathway by controlling the PEG molecular weight.

Fig. 6 Stacked $^{31}$P-NMR spectra for the nucleophilic degradation of Diazinon with piperidine performed in a mixture of 35 wt% PPG 400 + 15 wt% PEG 2000 + 50 wt% H$_2$O at 298K.

Fig. 7 Stacked $^{31}$P-NMR spectra for the nucleophilic degradation of Diazinon with piperidine performed in a mixture of 35 wt% PPG 400 + 15 wt% PEG 20000 + 50 wt% H$_2$O at 298K.

Even though the two reaction pathways identified in this work have been previously described for Diazinon’s degradation in other solvents such as ionic liquids, ACN, DMSO$^{17}$ and propylene carbonate$^{25},$ the relative products distribution reported is different from the obtained in this work. For instance, in ionic liquids, the preference for the aromatic pathway ranges between 28-50%; in ACN and DMSO it is about 50% and in propylene carbonate the degradation of Diazinon needs more than 100°C under microwave heating to be completed. In this work, we have found a preference of 80% and 100% for the aromatic pathway in PEG 600-PPG 400 and PEG 2000/20000-PPG 400 aqueous solutions, respectively. This means that the degradation of Diazinon can take place in these ABS without compromising the reaction rate, while taking advantage of these systems thermoreversible nature to easily and effectively separate the most abundant reaction product, the diethylthiophosphate (2), as demonstrated below.
Once the nucleophilic reactions reached equilibria, the systems were heated up to 313 K to induce phase separation and the bottom and top phases were carefully separated and analyzed by $^{31}$P-NMR and ESI-MS, whose results are shown in Fig. 8 for ABS formed by PEG 600 or PEG 20000, and in Fig. S3 in the ESI for PEG 2000.

From the $^{31}$P-NMR spectra shown in Fig. 8 and Fig. S3 in the ESI, it is clear that in ABS composed of PEG 2000 or PEG 20000 there is only one phosphorous product at 55 ppm, found in both phases. On the other hand, in the top phase of PEG 600 ABS, two phosphoryl signals at 55 and 50 ppm are seen, whereas in the bottom phase only one peak at 55 ppm appears. These results reveal that PEGs with higher molecular weights are not a promising separation approach for this kind of phosphoryl products. On the other hand, regarding the non-phosphorylated products (3 and 5 in Scheme 1), the ESI-MS spectra (Fig. S2 in the ESI) show that both of them are found in the top phase of the PEG 600-based ABS, whereas the bottom phase only has diethylthiophosphate (product 2, at 55 ppm), being this a promising option to separate the pesticide degradation products.

To the best of our knowledge there are no previous reports regarding the separation of degradation products of Diazinon. Most of the works found in the literature deal with analytical techniques to identify pesticides and their metabolites, mainly based on chromatographic techniques. In this work, we have identified a new and promising solvent to perform the nucleophilic degradation of Diazinon based on a PEG 600-PPG 400-water mixture, which acts as both an efficient reaction medium ($t_{1/2} = 927$ min) in comparison with the alkaline hydrolysis ($t_{1/2} = 145$ h, in similar conditions) and volatile organic solvents discussed above, but also as a relevant separation platform by simple applying changes in temperature.

**Conclusions**

In this work, ABS formed by PPG 400 and PEGs of different molecular weight were investigated as alternative solvents and simultaneous separation platforms for the nucleophilic degradation of the Diazinon pesticide. To this end, the ternary phase diagrams of ABS composed of water, PPG 400 and PEG 600, 1000, 2000, 4000, 6000, 8000, 10000 or 20000 were determined at 298 K (± 1 K) and atmospheric pressure. The ternary phase diagrams for ABS composed of water, PPG 400 and the extreme PEGs, namely PEG 600 or PEG 20000, were additionally determined at different temperatures (288, 298, 308, and 313 K (± 1 K)) and atmospheric pressure. The experimental data reveal an increase on the capability to form ABS with the increase of the PEG molecular weight and temperature. After the phase diagrams determination, the effect of PEG molecular weight in the partition of Diazinon in ABS formed by 35 wt% PPG 400 + 15 wt% PEG + 50 wt% H$_2$O was evaluated at 313K (±1K). The systems investigated allow extraction efficiencies ranging from 54.5% and 93.7%, with ABS formed by PEGs of higher molecular weight leading to higher extraction efficiencies of Diazinon to the PPG-rich phase. Based on these results, the nucleophilic degradation of Diazinon and the recovery of the products was carried out in the systems formed by 35 wt% PPG 400 + 15 wt% PEG (600, 2000 and 20000) + 50 wt% H$_2$O as a reaction media at 298 K, i.e. in the monophasic regime, to perform the nucleophilic substitution reaction of Diazinon with piperidine. The results showed that $t_{1/2}$ values decrease as the PEG molecular weight increases, getting half-life values of 1851 min (PEG 20000), 1273 min (PEG 2000) and 927 min (PEG 600). The solvents studied allowed the degradation of diazinon at a good rate in comparison with organic solvents at similar conditions, in a low-cost and easy to prepare reaction water-rich solvent. Results suggested that the reaction pathway and $t_{1/2}$ are dominated by the transfer phenomena, and that it would be possible to control the reaction pathway by controlling the PEG molecular weight.

By taking advantage of these systems thermoreversible nature, temperature was increased up to 313 K to induce ABS phase separation. From the $^{31}$P-NMR spectra it was observed the presence of phosphorous products in both phases of the ABS composed of PEG 20000 or PEG 2000, while in the system formed by PEG 600, both phosphorous products resulting from the nucleophilic degradation of Diazinon migrate toward the top phase and diethylthiophosphate only to the bottom phase. In this sense, with PPG 400 + PEG 600 + H$_2$O ABS it is possible to separate the most abundant degradation product of Diazinon found in the environment, opening an opportunity to develop
new techniques in the extraction of this kind of products from different environmental matrices to their subsequent removal.
